## STA 414/2104:

# Statistical Methods in Machine Learning II Week 6: HMMs and Variational Inference I 

Murat A. Erdoğdu, Piotr Zwiernik

University of Toronto

## Overview: part 1

- Hidden Markov Models
- Forward / Backward Algorithm
- Viterbi Algorithm

## Sequential data

We generally assume data was i.i.d, however this may be a poor assumption:

- Sequential data is common in time-series modelling (e.g. stock prices, speech, video analysis) or ordered (e.g. textual data, gene sequences).
- Recall the general joint factorization via the chain rule

$$
p\left(x_{1: T}\right)=\prod_{t=1}^{T} p\left(x_{t} \mid x_{t-1}, \ldots, x_{1}\right) \quad \text { where } p\left(x_{1} \mid x_{0}\right)=p\left(x_{1}\right)
$$

- But this quickly becomes intractable for high-dimensional data -each factor requires exponentially many parameters to specify as a function of $T$.
- So we made the simplifying assumption that our data can be modeled as a first-order Markov chain

$$
p\left(x_{t} \mid x_{1: t-1}\right)=p\left(x_{t} \mid x_{t-1}\right)
$$

## Sequential data

- In certain cases, Markov chain assumption is also restrictive.
- The state of our variables is fully observed. Hence, we introduce Hidden Markov Models

## Hidden Markov Models (HMMs)

- HMMs hide the temporal dependence by keeping it in the unobserved state.
- No assumptions on the temporal dependence of observations is made.
- For each observation $x_{t}$, we associate a corresponding unobserved hidden/latent variable $z_{t}$

- The joint distribution of the model becomes

$$
p\left(x_{1: T}, z_{1: T}\right)=p\left(z_{1}\right) \prod_{\substack{t=2 \\ \text { STA414-Week } 6}}^{T} p\left(z_{t} \mid z_{t-1}\right) \prod_{t=1}^{T} p\left(x_{t} \mid z_{t}\right)
$$

## Hidden Markov Models (HMMs)

Unlike simple Markov chains, the observations are not limited by a Markov assumption of any order. Assuming we have a homogeneous model, we only have to know three sets of distributions

1. Initial distribution: $\pi(i)=p\left(z_{1}=i\right)$. The probability of the first hidden variable being in state $i$ (often denoted $\pi$ )
2. Transition distribution:
$\Psi(i, j)=p\left(z_{t+1}=j \mid z_{t}=i\right) \quad i \in\{1, \ldots, k\}$. The probability of moving from hidden state $i$ to hidden state $j$.
3. Emission probability: $\psi_{t}(i)=p\left(x_{t} \mid z_{t}=i\right)$. The probability of an observed random variable $x$ given the state of the hidden variable that "emitted" it.

## HMMs: Objectives

We consider the following objectives:

1. Compute the probability of a latent sequence given an observation sequence.
That is, we want to be able to compute $p\left(z_{1: t} \mid x_{1: t}\right)$. This is achieved with the Forward-Backward algorithm.
2. Infer the most likely sequence of hidden states.

That is, we want to be able to compute

$$
z^{\star}=\underset{z_{1: T}}{\operatorname{argmax}} p\left(z_{1: T} \mid x_{1: T}\right)
$$

This is achieved using the Viterbi algorithm.

## Forward algorithm

- The goal is to recursively compute the filtered marginals,

$$
\alpha_{t}(j)=p\left(z_{t}=j \mid x_{1: t}\right)
$$

in an HMM,

- assuming that we know the initial $p\left(z_{1}\right)$, transition $p\left(z_{t} \mid z_{t-1}\right)$, and emission $p\left(x_{t} \mid z_{t}\right)$ probabilities $\forall t \in[1, T]$.
- This is a step in the forward-backward algorithm.

## Forward algorithm

The algorithm has two steps:

- First one is the prediction step, in which we compute the one-step-ahead predictive density; this acts as the new prior for time $t$ :

$$
\begin{aligned}
p\left(z_{t}=j \mid x_{1: t-1}\right) & =\sum_{i} p\left(z_{t}=j \mid z_{t-1}=i\right) p\left(z_{t-1}=i \mid x_{1: t-1}\right) \\
& =\sum_{i} \Psi(i, j) \alpha_{t-1}(i)
\end{aligned}
$$

- Next one is the update step,

$$
\begin{aligned}
\alpha_{t}(j) & =p\left(z_{t}=j \mid x_{1: t}\right)=p\left(z_{t}=j \mid x_{1: t-1}, x_{t}\right) \\
& \propto p\left(x_{t} \mid z_{t}=j, x_{1: t-1}\right) p\left(z_{t}=j \mid x_{1: t-1}\right) \\
& \propto p\left(x_{t} \mid z_{t}=j\right) p\left(z_{t}=j \mid x_{1: t-1}\right)=\psi_{t}(j) p\left(z_{t}=j \mid x_{1: t-1}\right)
\end{aligned}
$$

where the normalizing constant is

$$
Z_{t}=p\left(x_{t} \mid x_{1: t-1}\right)=\sum_{j} p\left(z_{t}=j \mid x_{1: t-1}\right) p\left(x_{t} \mid z_{t}=j\right)
$$

## Forward algorithm

- This process is called the predict-update cycle.
- Using matrix notation, we can write the update in the following simple form:

$$
\alpha_{t} \propto \psi_{t} \odot\left(\Psi^{T} \alpha_{t-1}\right)
$$

where

- $\psi_{t}(j)=p\left(x_{t} \mid z_{t}=j\right)$ is the local evidence at time $t$,
- $\Psi(i, j)=p\left(z_{t}=j \mid z_{t-1}=i\right)$ is the transition matrix,
- and $\odot$ is the Hadamard (entrywise) product.

## Forward-Backward algorithm

- The Forward-backward algorithm is used to efficiently estimate the latent sequence given an observation sequence under a HMM.
- That is, we want to compute

$$
p\left(z_{t} \mid x_{1: T}\right) \quad \forall_{t} \in[1, T]
$$

assuming that we know the initial $p\left(z_{1}\right)$, transition $p\left(z_{t} \mid z_{t-1}\right)$, and emission $p\left(x_{t} \mid z_{t}\right)$ probabilities $\forall t \in[1, T]$.

## Forward-Backward algorithm

This task of hidden state inference breaks down into the following:

- Filtering: compute posterior over current hidden state, $p\left(z_{t} \mid x_{1: t}\right)$.
- Prediction: compute posterior over future hidden state, $p\left(z_{t+k} \mid x_{1: t}\right)$.
- Smoothing: compute posterior over past hidden state, $p\left(z_{k} \mid x_{1: t}\right) \quad 1<k<t$.
The probability of interest, $p\left(z_{t} \mid x_{1: T}\right)$ is computed using a forward and backward recursion
- Forward Recursion: $p\left(z_{t} \mid x_{1: t}\right)$
- Backward Recursion: $p\left(x_{1+t: T} \mid z_{t}\right)$

## Forward-Backward algorithm

We can break the chain into two parts, the past and the future, by conditioning on $z_{t}$ :

- We have

$$
\begin{aligned}
\gamma_{t}=p\left(z_{t} \mid x_{1: T}\right) & \propto p\left(z_{t}, x_{1: T}\right) \\
& =p\left(z_{t}, x_{1: t}\right) p\left(x_{t+1: T} \mid z_{t}, x_{1: t}\right) \\
& =p\left(z_{t}, x_{1: t}\right) p\left(x_{t+1: T} \mid z_{t}\right) \\
& \propto(\text { Forward Recursion }) \text { (Backward Recursion) }
\end{aligned}
$$

- The third line is arrived at by noting the conditional independence $x_{t+1: T} \perp x_{1: t} \mid z_{t}$.
- We know how to perform forward recursion from the previous part.

## Backward recursion

## In the backward pass,

$$
\begin{aligned}
\beta_{t}(i) & =p\left(x_{t+1: T} \mid z_{t}=i\right) \\
& =\sum_{j} p\left(z_{t+1}=j, x_{t+1: T} \mid z_{t}=i\right) \\
& =\sum_{j} p\left(x_{t+2: T} \mid z_{t+1}=j, z_{t}=i, x_{t+1}\right) p\left(x_{t+1} \mid z_{t+1}=j, z_{t}=i\right) p\left(z_{t+1}=j \mid z_{t}=i\right) \\
& =\sum_{j} p\left(x_{t+2: T} \mid z_{t+1}=j\right) p\left(x_{t+1} \mid z_{t+1}=j\right) p\left(z_{t+1}=j \mid z_{t}=i\right) \\
& =\sum_{j} \beta_{t+1}(j) \psi_{t+1}(j) \Psi(i, j)
\end{aligned}
$$

- Notice that our backward recursion contains our emission, $\psi_{t+1}=p\left(x_{t+1} \mid z_{t+1}\right)$ and transition, $\Psi=p\left(z_{t+1} \mid z_{t}\right)$ probabilities.

## Backward recursion

- In vector notation

$$
\beta_{t}=\Psi\left(\psi_{t+1} \odot \beta_{t+1}\right)
$$

where $\beta_{T}(i)=1$.

- Once we have the forward and the backward steps complete, we can compute

$$
\gamma_{t}(i) \propto \alpha_{t}(i) \beta_{t}(i)
$$

which is called the forward-backward algorithm.

- Recall

$$
\begin{aligned}
\gamma_{t}=p\left(z_{t} \mid x_{1: T}\right) & \propto p\left(z_{t}, x_{1: t}\right) p\left(x_{t+1: T} \mid z_{t}\right) \\
& \propto(\text { Forward Recursion }) \text { (Backward Recursion) }
\end{aligned}
$$

## Viterbi algorithm

- The Viterbi algorithm (Viterbi 1967) is used to compute the most probable sequence.

$$
\hat{z}=\arg \max _{z_{1: T}} p\left(z_{1: T} \mid x_{1: T}\right)
$$

- Since this is MAP inference, we might think of replacing sum-operators with max-operators, just like we did in sum-product and max-product.
- But this, in general, will lead to incorrect results.
- In Viterbi algorithm, the forward pass does use max- product, but the backwards pass uses a traceback procedure to recover the most probable path.

## Viterbi algorithm

- Let's define

$$
\delta_{t}(j)=\max _{z_{1}, ., z_{t-1}} p\left(z_{1: t-1}, z_{t}=j \mid x_{1: t}\right)
$$

which is the probability of ending up in state $j$ at time $t$, by taking the most probable path.

- We notice that

$$
\begin{aligned}
\delta_{t}(j) & =\max _{z_{1}, ., z_{t-1}} p\left(z_{1: t-1}, z_{t}=j \mid x_{1: t}\right) \\
& \propto \max _{z_{1}, ., z_{t-1}} p\left(z_{1: t-2}, z_{t-1}=i \mid x_{1: t-1}\right) p\left(z_{t}=j \mid z_{t-1}=i\right) p\left(x_{t} \mid z_{t}=j\right) \\
& =\max _{i} \delta_{t-1}(i) \Psi(i, j) \psi_{t}(j)
\end{aligned}
$$

- Let's keep track of the most likely previous state,

$$
\theta_{t}(j)=\arg \max _{i} \delta_{t-1}(i) \Psi(i, j) \psi_{t}(j)
$$

## Viterbi algorithm

- Initialize the algorithm with

$$
\delta_{1}(j)=\pi_{j} \psi_{1}(j)
$$

where $\pi_{j}=p\left(z_{1}=j\right)$

- and terminate with

$$
z_{T}^{*}=\arg \max _{i} \delta_{T}(i)
$$

- Then, we compute the most probable sequence of states using traceback:

$$
z_{t}^{*}=\theta_{t+1}\left(z_{t+1}^{*}\right)
$$

## Summary: HMMs

- HMMs hide the temporal dependence by keeping it in the unobserved state.
- No assumptions on the temporal dependence of observations is made.
- Forward-backward algorithm can be used to find "beliefs"
- Viterbi algorithm can be used to do MAP.
- Next: Variational inference.

## Overview: part 2

- Variational Inference
- M-projection
- I-projection
- Naive mean-field approach

## Posterior Inference for Latent Variable Models

We've worked with a few latent variable models, such as the generative image model and the trueskill model.
These models have a factorization $p(x, z)=p(z) p(x \mid z)$ where

- $x$ are the observations or data,
- $z$ are the unobserved (latent) variables
- $p(z)$ is usually called the prior
- $p(x \mid z)$ is usually called the likelihood
- The conditional distribution of the unobserved variables given the observed variables (aka the posterior) is

$$
p(z \mid x)=\frac{p(x \mid z) p(z)}{p(x)}=\frac{p(x \mid z) p(z)}{\int p(x, z) d z}
$$

## Prior:

image 20220212225218.png

Says we're very uncertain about both player's skill.

Likelihood:

This is the part of the model that gives meaning to the latent variables.

## Posterior:

image 20220212225421.png

The posterior isn't Gaussian anymore.

Posterior after A beats B 10 times:
image 20220212225500.png
Now the posterior is certain that A is better than B .

Posterior after both beat each other 10 times:

Now the posterior is certain that neither player is much better than the other, but is uncertain how good they both are in an absolute sense.

## What is hard to compute about the posterior?

- The integral $p(x)=\int p(x, z) d z$ is intractable whenever $z$ is high dimensional. This makes evaluating or sampling from the normalized posterior $p(z \mid x)$ for a given $x$ and $z$ also intractable.
- Here is a list of operations that are expensive:
- Computing a posterior probability: $p(z \mid x)=\frac{p(z) p(x \mid z)}{p(x)}$
- Computing the evidence / marginal likelihood $p(x)=\int p(z, x) d z$
- Useful for choosing between models, or fitting model parameters.
- Computing marginals of $p\left(z_{1} \mid x\right)=\int p\left(z_{1}, z_{2}, \ldots z_{D} \mid x\right) d z_{2}, d z_{3}, \ldots d z_{D}$
- E.g. finding the posterior over a single tennis player's skill given all games.
- Sampling $z \sim p(z \mid x)$
- Useful for summarizing which hypotheses are likely given the data, making predictions, and decisions.

## Variational methods

- Variational inference is closely related to the calculus of variations, developed in the 1700s by Euler, Lagrange.
- Variational inference is an approximate inference method where we seek a tractable (e.g., factorized) approximation to the target intractable distribution.

## Variational methods

To be more formal, variational inference works as follows:

- Choose a tractable distribution $q(z) \in Q$ from a feasible set $Q$. This distribution will be used to approximate $p(z \mid x)$.
- For example, $q(z)=\mathcal{N}(z \mid \mu, \Sigma)$. The idea is that we'll try choose a $Q$ that makes $q(z)$ a good approximation of the true posterior $p(z \mid x)$.
- Encode some notion of "difference" between $p(z \mid x)$ and $q$ that can be effciently estimated. Usually we will use the KL divergence.
- Minimize this difference. Usually we will use an iterative optimization method.

Player A Skill

- Whatever feasible set we choose for $Q$, it's usually not the case that there is any $q \in Q$ that exactly matches the true posterior.
- But computing the true posterior is intractable, so we have to take a shortcut somewhere.

## How to measure closeness: KL divergence

We will measure the difference between $q$ and $p$ using the Kullback-Leibler divergence

$$
\begin{aligned}
K L(q(z) \| p(z \mid x)) & =\int q(z) \log \frac{q(z)}{p(z \mid x)} d z \\
& =\underset{z \sim q}{\mathbb{E}} \log \frac{q(z)}{p(z \mid x)}
\end{aligned}
$$

Properties of the KL Divergence

- $K L(q \| p) \geq 0$
- $K L(q \| p)=0 \Leftrightarrow q=p$
- $K L(q \| p) \neq K L(p \| q)$
- KL divergence is not a metric, since it's not symmetric

## Which direction of KL to use? $K L(q \| p)$ vs $K L(p \| q)$

- We could minimize $K L(q \| p)$ or $K L(p \| q)$
- Which one to choose?
- As always, we will go with the tractable one.

## Information (I-)Projection:

I-projection: $q^{*}=\arg \min _{q \in Q} K L(q \| p)=\mathbb{E}_{x \sim q(x)} \log \frac{q(x)}{p(x)}$ :

- $p \approx q \Longrightarrow K L(q \| p)$ small
- I-projection underestimates support, and does not yield the correct moments.
- $K L(q \| p)$ penalizes $q$ having mass where $p$ has none.
$p(x)$ is mixture of two 2 D Gaussians and $Q$ is the set of all 2D Gaussian distributions (with arbitrary covariance matrices)

## Moment (M-)projection

M-projection: $q^{*}=\arg \min _{q \in Q} K L(p \| q)=\mathbb{E}_{x \sim p(x)} \log \frac{p(x)}{q(x)}$ :

- $p \approx q \Longrightarrow K L(p \| q)$ small
- $K L(p \| q)$ penalizes $q$ missing mass where $p$ has some.
- M-projection yields a distribution $q(x)$ with the correct mean and covariance.
$p(x)$ is mixture of two 2D Gaussians and $Q$ is the set of all 2D Gaussian distributions (with arbitrary covariance matrices)

## Maximum entropy interpretation

- A related quantity is the entropy:

$$
H(p)=-\mathbb{E}_{x \sim p(x)} \log p(x)
$$

measuring the uncertainty in the distribution $p$.

- Consider the optimization problem

$$
\begin{aligned}
& \operatorname{maximize} H(p) \\
& \text { subject to } \mathbb{E}_{x \sim p(x)}\left[f_{i}(x)\right]=t_{i} \text { for } i=1, . ., k
\end{aligned}
$$

- Theorem: Exponential family of distributions maximize the entropy $H(p)$ over all distributions satisfying

$$
\mathbb{E}_{x \sim p(x)}\left[f_{i}(x)\right]=t_{i} \text { for } i=1, . ., k
$$

- In M-projection, if $Q$ is set of exponential families, then the expected sufficient statistics wrt $q^{*}(x)$ is the same as that wrt $p(x)$.
- M-projection require expectation wrt $p$, hence intractable.
- Most variational inference algorithms make use of the I-projection.

## Mean-field approach

- Say we have an arbitrary MRF:

$$
p(x \mid \theta)=\exp \left\{\sum_{c \in \mathcal{C}} \phi_{c}\left(x_{c}\right)-\log Z(\theta)\right\}
$$

- We find an approximate distribution $q(x) \in Q$ by performing I-projection to $p(x)$.

$$
\begin{aligned}
q^{*}= & \arg \min _{q \in Q} K L(q \| p)=\mathbb{E}_{x \sim q(x)} \log \frac{q(x)}{p(x \mid \theta)} \\
& \arg \min _{q \in Q} K L(q \| p)=\mathbb{E}_{x \sim q(x)}\left[\log q(x)-\sum_{c \in \mathcal{C}} \phi_{c}\left(x_{c}\right)+\log Z(\theta)\right] \\
= & \arg \max _{q \in Q} \sum_{c \in \mathcal{C}} \mathbb{E}_{q}\left[\phi_{c}\left(x_{c}\right)\right]+H(q)
\end{aligned}
$$

- For tractability, we need a nice set $Q$. If $p \in Q$, then $q^{*}=p$. But this almost never happens.

## Naive Mean-Field

- One way to proceed is the mean-field approach where we assume:

$$
q(x)=\prod_{i \in V} q_{i}\left(x_{i}\right)
$$

the set $Q$ is composed of those distributions that factor out.

- Using this in the maximization problem, we can simplify things

$$
q^{*}=\arg \max _{q \in Q} \sum_{c \in \mathcal{C}} \sum_{x_{c}} q\left(x_{c}\right) \phi_{c}\left(x_{c}\right)+H(q)
$$

- We notice $q\left(x_{c}\right)=\prod_{i \in c} q_{i}\left(x_{i}\right)$ and also

$$
\begin{aligned}
H(q) & =\mathbb{E}_{q}[-\log q(x)]=-\sum_{x} q(x) \log q(x) \\
& =-\sum_{x} q(x)\left[\sum_{i} \log q_{i}\left(x_{i}\right)\right] \\
& =-\sum_{i} \sum_{x}\left[q_{i}\left(x_{i}\right) \log q_{i}\left(x_{i}\right)\right] \frac{q(x)}{q_{i}\left(x_{i}\right)} \\
& =-\sum_{i} \sum_{x_{i}}\left[q_{i}\left(x_{i}\right) \log q_{i}\left(x_{i}\right)\right] \sum_{x \backslash x_{i}} \frac{q(x)}{q_{i}\left(x_{i}\right)} \\
& =-\sum_{i} \sum_{x_{i}}\left[q_{i}\left(x_{i}\right) \log q_{i}\left(x_{i}\right)\right] \\
& =\sum_{i} H\left(q_{i}\right)
\end{aligned}
$$

## Example: Pairwise MRF

- Thus the final optimization problem reduces to

$$
\begin{aligned}
q^{*}= & \arg \max _{q} \sum_{c \in \mathcal{C}} \sum_{x_{c}} \phi_{c}\left(x_{c}\right) \prod_{i \in c} q_{i}\left(x_{i}\right)+\sum_{i} H\left(q_{i}\right) \\
& \text { subject to: } q_{i}\left(x_{i}\right) \geq 0 \text { and } \sum_{x_{i}} q_{i}\left(x_{i}\right)=1
\end{aligned}
$$

- Let's further simplify the setting and assume that we have a pairwise MRF. Then the optimization problem becomes

$$
q^{*}=\arg \max _{q} \sum_{(i, j) \in \mathcal{E}} \sum_{x_{i}, x_{j}} \phi_{i j}\left(x_{i}, x_{j}\right) q_{i}\left(x_{i}\right) q_{j}\left(x_{j}\right)-\sum_{i} \sum_{x_{i}} q_{i}\left(x_{i}\right) \log \left(q_{i}\left(x_{i}\right)\right)
$$

$$
\text { subject to: } q_{i}\left(x_{i}\right) \geq 0 \text { and } \sum_{x_{i}} q_{i}\left(x_{i}\right)=1
$$

## Coordinate maximization

This problem is hard as it has many local maxima! But we can still try to optimize using block coordinate ascent.

- Initialize $\left\{q_{i}\left(x_{i}\right)\right\}_{i \in V}$ uniformly
- Iterate over $i \in V$
- Greedily maximize the objective over $q_{i}\left(x_{i}\right)$
- This is equivalent to: $q_{i}\left(x_{i}\right) \propto \exp \left\{\sum_{j \in N(i)} \sum_{x_{j}} q_{j}\left(x_{j}\right) \phi_{i j}\left(x_{i}, x_{j}\right)\right\}$
- which follows from: write the Lagrangian, take the derivative, set to zero, and solve
- Repeat until convergence.

This is guaranteed to converge but can converge to local optima.

## Summary

- Approximate the complex (intractable) distribution with a simpler (tractable) distribution
- I-projection \& M-projection measure the distance to true posterior
- Mean field approximation is a way to simplify the set of distributions
- More variational inference after midterm (which is in 2 weeks).
